ABSTRACT

There is an increasing awareness of the association between mitral valve prolapse and sudden cardiac death. There are several clinical risk factors associated with an increased risk of mitral valve prolapse-related sudden cardiac death, most of which can be evaluated with noninvasive diagnostic modalities. For example, characteristic changes on the electro-cardiogram (T-wave inversions in the inferior leads), complex ventricular ectopy, a spiked configuration of the lateral annular velocities by echocardiography, and evidence of myocardial fibrosis by cardiac magnetic resonance imaging have all been implicated as markers of risk. Herein, the authors review the reported incidence of sudden death to mitral valve prolapse, the clinical profile of at-risk patients, and the basic components necessary to initiate and perpetuate ventricular arrhythmias (substrate and trigger) as well as potential interventions to consider for those at highest risk. (J Am Coll Cardiol 2018;72:2904-14) © 2018 Published by Elsevier on behalf of the American College of Cardiology Foundation.

itral valve prolapse (MVP), estimated to affect 1% to 3% of the general population, is classically defined as a superior displacement of the mitral leaflet(s) of >2 mm during systole and myxomatous degeneration of the mitral leaflets, resulting in a maximal leaflet thickness of at least 5 mm during diastasis (1). MVP carries a heterogenous prognosis with clinical outcomes dependent on multiple variables, including patient age, degree of mitral regurgitation (MR), left ventricular (LV) ejection fraction, ventricular ectopy, and atrial diameter (2). The adverse sequelae of primary MVP include significant MR, heart failure, infective endocarditis, stroke, cardiac arrhythmias, and, perhaps the least appreciated but most devastating complication, sudden cardiac death (SCD) (3). Although the association

between MVP and SCD was first reported decades ago, the risk was initially believed to be exceedingly small, and there was scant literature to suggest otherwise (4). More contemporary observational studies suggest that MVP-related SCD, owing to sustained ventricular arrhythmias (VAs), may occur more frequently, with an estimated annual risk of 0.2% to 1.9% (3,5-8). Consequently, there is an increasing interest in MVP-related SCD as well as effective techniques to identify those patients at higher risk for a fatal arrhythmic event. Recent studies have yielded new insights into the pathophysiology and risk factors for the development of VAs in patients with MVP. This review focuses on arrhythmic causes of SCD in patients with degenerative MVP (Barlow's disease).

INCIDENCE OF SCD ATTRIBUTED TO MVP

The reported incidence of SCD due to mitral valve prolapse varies depending on the methods used to evaluate the cause of death (e.g., autopsy vs. survivors), the study population (e.g., age, athletes), available clinical information (e.g., electrocardiogram [ECG], echocardiogram), and forensic analysis performed (e.g., genetics) (9).

Autopsy-based studies have reported wide incidence rates for MVP-related SCD. This variability exists in part because of the uncertain cause-effect relationship between the finding of MVP at autopsy and the arrhythmic SCD (10). Therefore, the confirmed presence of MVP on examination is rarely classified as "unequivocally related" to the SCD event, even when exhaustive examinations cannot identify another potential etiology. Rather, MVP it is more often classified as "undetermined" or "probably related" to the fatal event. For example, an autopsy study could not determine the presumptive cause of death in 50% of the young women (35 to 44 years of age) studied, and so those with those cases (n = 13)were classified as "sudden cardiac death of unexplained etiology." However, of those "unexplained" cases, more than one-half were noted to have mitral valve prolapse at autopsy (11). This lack of classification may result in an underestimation of the true incidence of MVP-related SCD, especially when autopsy studies show that MVP remains one of the most common causes of death in otherwise healthy young patients where MVP is offered as a classification (4,12,13).

A 21-year prospective clinical-pathological investigation in Italy (<35 years of age) found MVP to be the third most common cardiac condition associated with SCD with an incidence of 12%, with arrhythmogenic right ventricular dysplasia (24%) and atherosclerotic coronary artery disease (20%) being the only diagnoses that were more common (14). In registries of competitive and noncompetitive athletes, the incidence of SCD attributable to MVP ranged from 2% to 4%, similar to community-based studies of nonathletes (2.3%) (5,13). The true annual risk of SCD for the individual patient with MVP, however, remains unknown. While observational studies have estimated the risk at 0.9% to 1.9% per year, there is significant heterogeneity in methodology and study populations. Additionally, in studies that do report the incidence of MVP-related sudden death, it remains unclear what valve morphology criteria were present (e.g., redundant and thickened), which could impact the true estimation of its association. Select studies that report the incidence of MVPrelated SCD are shown in **Table 1**. Finally, while the denominator is large (i.e., the number of patients with MVP), the precise numerator (i.e., the number of patients who have aborted or fatal VAs) is unknown, due to the absence of large longitudinal registries. Therefore, it is prudent to focus on patients with additional risk factors for the development of sustained VAs (8).

RISK FACTORS

Several clinical risk factors appear to be associated with an increased risk of SCD in patients with MVP (**Central Illustration**). For the purposes of this review, we have separated them by baseline characteristics and diagnostic modality: electrocardiography, echocardiographic, and magnetic resonance imaging (5,6,15).

BASELINE CHARACTERISTICS

MVP related life-threatening VAs appear to occur more often in young females, with some studies demonstrating that 70% to 90% of affected individuals are women (16). The reason for this gender discrepancy is unknown and may be multifactorial. MVP is more common in women and they are more likely to have bileaflet prolapse and more valve thickening, and less likely to undergo valve surgery (17).

ELECTROCARDIOGRAPHY

A majority of patients (>75%) with MVP-related SCD demonstrate characteristic T-wave abnormalities on the surface ECG with biphasic or inverted T-waves in the inferior leads (II, III, aVF) (6,15) (Figure 1). In our opinion, the presence of this finding in MVP patients should prompt the clinician to further investigate an individuals' risk profile, acknowledging, however, that this finding alone is not enough to consider a patient at high risk, as inverted T waves can be found in up to 40% of MVP patients without a history of sustained VAs (18).

Premature ventricular contractions (PVC) are a common finding in the general population of MVP patients with and without SCD. Although patients without accompanying MR exhibit fewer complex PVCs, they are still a relatively common finding (\sim 40% to 50%) compared with the general population (19). Complex PVCs usually refer to those that

ABBREVIATIONS AND ACRONYMS

CMR = cardiac magnetic resonance

are multiform (pleomorphic) and occur as couplets or nonsustained ventricular tachycardia (VT) (20). The dominant PVC morphologies in MVP patients are those arising from the papillary muscle region and the outflow tract. The ectopy is presumed to be at least in part due to regional stretch, either as a consequence of direct mechanical forces or triggered activity due to damaged tissue with abnormal Ca²⁺ handling and evoked delayed afterdepolarizations (21). The presence of PVCs alone, even pleomorphic PVCs, is not enough to risk stratify a patient as it is a common finding, but it should alert the clinician to consider additional risk stratification. Perhaps a more important marker of SCD is the origin of the PVC. In a series of consecutive bileaflet MVP patients undergoing catheter ablation, a Purkinje origin PVC was identified as the ventricular fibrillation trigger in all 6 of the patients who had a prior history of cardiac arrest (7). As concluded by the authors, arrhythmic mitral valve prolapse (bileaflet) is characterized by fascicular and papillary muscle PVCs that trigger ventricular fibrillation, suggesting a central role of the Purkinje system in this condition.

ECHOCARDIOGRAPHY

Bileaflet MVP has been proposed as a high-risk feature for SCD, but there have been conflicting results regarding long-term prognosis in these patients (6,15,22). A review of 1,200 unexplained out-of-hospital cardiac arrest patients at the Mayo Clinic found a 42% prevalence of bileaflet MVP in a series of 24 young patients who survived an idiopathic out-of-hospital cardiac arrest (15). However, it should be noted that in another large retrospective series from the same institution, isolated bileaflet MVP, without additional risk factors, did not appear to significantly increase the risk of SCD or need for defibrillator implant compared with single-leaflet MVP, suggesting the importance of confirming the presence of additional risk factors (22).

Mitral regurgitation frequently develops occurs in patients with MVP and its severity appears to have a significant association with VAs in MVP, although, again, there are conflicting data (23). In 1 observational series, moderate-severe MR was an independent predictor of VAs (relative risk: 8.42); however, MVP-related SCD is also known to occur in patients with minimal-mild MR (23,24).

An easily obtainable and recently reported echocardiographic marker of arrhythmic risk involves the measurement of myocardial velocities. In patients with myxomatous bileaflet mitral valve prolapse, lateral mitral annular velocities were quantified with Doppler tissue imaging. Patients were divided into those with "Pickelhaube sign" (Figure 1), defined as a peak systolic lateral mitral annulus velocity of \geq 16 cm/s, and those without (<16 cm/s) (25).

The patients meeting this criterion were more likely to have had a malignant VA (67% vs. 22%; p < 0.08). Furthermore, delayed gadolinium enhancement (by magnetic resonance imaging [MRI]) was only present in the group with the Pickelhaube sign (33%) and not in those without it. The authors concluded that the presence of a Pickelhaube sign may be an indicator of a malignant phenotype of myxomatous bileaflet mitral valve prolapse. However, further investigation is needed to confirm their findings.

CARDIAC MRI

Cardiac MRI can help define and characterize the composition of the myocardium and identify specific arrhythmic risk factors, such as endocardial fibrosis (6,26). Basso et al. (6) examined 43 cases of SCD in young patients with MVP from the Italian cardiac pathology registry of SCD victims and performed cardiac magnetic resonance (CMR) and histopathological correlation (7). In patients with SCD and complex VAs, they found a high percentage exhibited evidence of either focal LV papillary muscle fibrosis (88%) or inferobasal fibrosis (93%) (Figure 1). As expected, late gadolinium enhancement (LGE) distribution on CMR correlated with histopathological fibrosis. These observations were confirmed in another independent cohort of 3,680 autopsies, of which MVP accounted for 62 (1.7%) cases (27). The authors identified LV fibrosis in 74% of cases with fibrosis involving 1 or both papillary muscles (predominantly the posteromedial papillary muscle)

and the adjacent LV wall (predominantly the posteroinferior LV wall). The association between MVP and myocardial replacement fibrosis was recently further characterized by an elegant study of patients with primary MR due to either MVP (n = 177) or non-MVP (n = 179) etiologies. The authors demonstrated that MVP is associated with more LV fibrosis on MRI compared with non-MVP-related MR, and the fibrosis increases with MR severity, tends to occur in specific areas of the LV (suggestive of a mechanistic association), and is associated with sustained VT or ventricular fibrillation (VF). Specifically, LV fibrosis was present in 36.7% of MVP patients, compared with only 6.7% of non-MVP patients (p < 0.001). Furthermore, in the MVP patients, replacement fibrosis (midwall striae or patchy pattern) was most commonly found in the basal inferolateral wall (31.1%) followed by the basal inferior wall (10.7%). During follow-up, arrhythmic events (defined as SCD, or spontaneous or induced sustained VT) occurred in 4.5% (n = 8) of the MVP patients. The highest arrhythmic event rate was seen in MVP patients with replacement fibrosis (7.7%), followed by MVP patients without replacement fibrosis (2.7%) and non-MVP patients (0.6%; p < 0.01) (28).

The presence of diffuse subclinical interstitial fibrosis by CMR in patients with MVP with MR was also reported by Bui et al. (29). They showed that the presence of diffuse nonfocal subclinical ventricular fibrosis was associated with complex VAs. The authors suggested that subclinical diffuse fibrosis maybe a precursor of focal fibrosis in MVP or a separate disease entity involving up-regulation of fibrotic markers could be a marker for early identification of patients at risk of SCD.

Recently, mitral annulus disjunction (MAD) was reported to be a constant component of arrhythmic MVP with LV fibrosis (30). MAD is detachment of the roots of the annulus from the ventricular myocardium (i.e., ventriculoannular detachment), which is localized to the base of the posterior leaflet (31). In a study including 36 patients with MVP, MAD was significantly longer (4.8 mm) in those with LGE on MRI, compared with those who did not have LGE on MRI (1.8 mm; p < 0.001). However, the study did not provide a specific threshold limit (distance) of MAD that was associated with an increased risk of VAs; therefore, these findings require further validation in independent cohorts. Figure 2 is an example of a patient who first presented with SCD due to ventricular fibrillation and MAD (12.7 mm) by MRI. It should also be noted that transthoracic echocardiography has been used to assess MAD in patients with myxomatous mitral valve disease, and the severity of MAD is associated with VA burden. For example, a disjunction length of >8.5 mm correctly identified 67% of the patients who exhibited nonsustained VT on Holter monitoring (32).

PROPOSED MECHANISM OF VAs: SUBSTRATE, TRIGGER, AND TRANSIENT MODULATOR

Two common findings in patients with MVP-related SCD are: 1) LV myocardial fibrosis (substrate); and 2) complex ventricular ectopy (trigger). Perhaps a consequence of mechanical traction exerted by the prolapsing leaflet, the fibrosis is most often localized to the inferolateral base of the left ventricle or the papillary muscles, which are most susceptible to the mechanical stretch forces exerted by the billowing leaflets (14). With continued mechanical traction by the prolapsing leaflet, myocardial hypertrophy, and a replacement fibrosis can occur in those structures that support the mitral apparatus-the basal and midinferolateral ventricle and the papillary muscles (33). Additionally, it has been postulated that friction between the chordae and the LV endocardium can result in "friction lesions," characterized by the development of endocardial fibrosis between the papillary muscle and the annulus (34). The mechanically induced LV fibrosis likely acts as the substrate, which increases the vulnerability by either triggered activity or re-entry of these patients to both the development and maintenance of sustained ventricular tachyarrhythmia (35). **Figure 3** is an example of a middle-aged man who was being routinely followed for asymptomatic MVP but experienced a witnessed out-of-hospital cardiac arrest (VF); he was subsequently found to have delayed enhancement in the posterobasal LV.

PREMATURE VENTRICULAR CONTRACTIONS. As noted previously, a majority of patients with MVP who experienced SCD have a history of complex PVCs (**Figure 1**). Acute myocardial stretch can cause shortening of the action potential duration, a decrease in resting diastolic potential, and the development of

stretch-activated early afterdepolarizations (36,37). The papillary muscles are exposed to these acute stretch forces by the prolapsing leaflet, and the papillary muscles distal Purkinje fibers which are prone to afterdepolarization and abnormal automaticity. In fact, in patients with bileaflet prolapse and prior cardiac arrest undergoing catheter ablation, Purkinje signals commonly precede the VF, triggering PVCs (15).

TRANSIENT MODULATOR: AUTONOMIC NERVOUS SYSTEM AND CATECHOLAMINES. Autonomic dysfunction, including elevated sympathetic and diminished vagal tone, are known to occur in patients with MVP (38). This hyperadrenergic state can increase the frequency of ventricular ectopy, as well as the predisposition of the ventricular myocardium to that ectopic activity (23,38). The prolapsing mitral valve delivers traction on the papillary muscles, activating the local stretch receptors and causing membrane depolarization of the nerve endings with abnormal mechanoelectrical feedback to the central nervous system causing VT or VF (39,40). In addition, the enhanced catecholamine levels can cause downstream ion-channel modulation and Ca⁺² loading in the sarcoplasmic reticulum, resulting in delayed afterdepolarization and subsequently contributing to VAs (41,42). Ultimately, it is the combination of circumstances, such as short-coupled mechanically triggered PVCs from a structural or fibrotic abnormality from the mitral valve apparatus combined with heightened autonomic tone, that sets the stage for the development of SCD in the vulnerable patient. The Central Illustration depicts the interaction among the substrate (scar), trigger (PVCs), and a transient event

(e.g., heightened autonomic tone) that can precipitate a sustained VA.

RISK STRATIFICATION

Although there are several risk factors that predict SCD in MVP, there is no single risk factor that has proved to be a consistent predictor of malignant VAs and SCD. Furthermore, it is not yet known which combination of risk factors predisposes patients to higher risk. The challenge of risk stratification in MVP is identifying the high-risk patient concealed within a large population of low-risk patients. Nevertheless, we believe that a focused work-up can be performed to stratify the patient into a low-risk or high-risk category (Central Illustration). As previously mentioned, most patients with MVP-related SCD have complex ventricular ectopy (trigger) and myocardial scar (substrate), and therefore a work-up should include an assessment of these factors. The available literature suggests that female sex, bileaflet MVP, history of complex ventricular ectopy, and LGE on CMR are readily identifiable features that can be used to categorize patients as higher or lower risk (6,15,26). With regard to detecting nonsustained VT, in a patient population of MVP patients without arrhythmic symptoms, the estimated sensitivity of the 12-lead ECG, treadmill ECG, and 24-h ambulatory Holter monitor was 17%, 50%, and 83%, respectively (43). In our own practice, we recommend extended rhythm monitoring (either 24-h Holter or 7-day external event recorder) to assess the burden of VAs, even in asymptomatic patients. In patients with MVP and unexplained syncope, we would recommend a thorough diagnostic evaluation to determine if the patient has true arrhythmic syncope. Clinical features suggestive of arrhythmic syncope include syncope during strenuous exercise, while sitting or in the supine position, sudden-onset palpitations before the syncopal event, and absence of any warning symptoms immediately prior. For patients with MVP, suspected arrhythmic syncope, and evidence of myocardial scar, it would be appropriate to consider either an electrophysiology study. If the electrophysiology study is negative or not performed, a loop recorder implant for long-term rhythm monitoring should be strongly considered in any patient, especially if other high-risk features are present (e.g., bileaflet prolapse, complex ventricular ectopy) (44).

For patients who have evidence of complex VAs or echocardiographic evidence of mechanical traction of the papillary muscles or ventricular myocardium (e.g., Pickelhaube sign), we recommend CMR to assess for myocardial scar. In our own practice, we consider performing an electrophysiology study for risk stratification for patients with multiple risk factors, such as those with evidence of a trigger (pleomorphic PVCs) and substrate (myocardial scar). It should be acknowledged that programmed electrical ventricular stimulation to risk stratify MVP patients is not well established, as it is with other substrates that predispose to SCD (45). The induction of polymorphic VT and VF with aggressive stimulation protocols in patients with a history of complex VAs is a nonspecific finding and does not necessarily predict future risk of SCD. However, the few studies assessing the role of programmed ventricular stimulation in an MVP patient population did not include more conventional risk factors, such as presence of myocardial scar. We define a positive electrophysiology study as sustained monomorphic VT, which is induced with up to 3 ventricular extrastimuli or polymorphic VT or VF induced with up to 2 ventricular extrastimuli. In those patients with a "positive" electrophysiology study, we recommend implantation of an implantable cardioverter-defibrillator. However, it is important to recognize that additional studies are needed to understand the prognostic ability of programmed electrical ventricular stimulation in this heterogenous patient population.

RECOMMENDATIONS

The American Heart Association/European Society of Cardiology guidelines for VAs and SCD have no specific recommendations for the risk stratification of SCD in MVP (46). The management of low-risk MVP patients with pleomorphic VAs needs to be conservative, with surveillance cardiac monitoring with or without medications. Beta-blockers are the preferred first-line agents for the management of symptomatic or asymptomatic nonsustained or sustained VAs (46). It is recommended that patients avoid stimulants such as caffeine, alcohol, tobacco, and other illicit drugs that can increase catecholamine levels (47). Recommendations for exercise are included in the Online Appendix. Online Figure 1 is an example of exercise-induced ventricular tachycardia.

CATHETER ABLATION

Due to the diverse conditions that are involved in initiating malignant VAs in MVP, it can be appreciated that catheter ablation is reserved for cases where electrical triggers of VT or VF can be mapped and identified or for scar-related re-entrant VT (7,48). As for the former, the procedure involves mapping of

PVC triggers, which are often preceded by Purkinje potentials, and often located on the papillary muscles or within the fascicular conduction system (49). A small case series including 14 patients with bileaflet MVP with and without VF arrest who underwent catheter ablation reported a high rate of acute procedural success (89%) and a substantial reduction in implantable cardioverter-defibrillator therapies (7). As mentioned, there is a subset of patients who can develop scar-related re-entrant VT. The scar is often located at the inferobasal or inferolateral LV, the typical locations identified in imaging studies of MVP patients. **Figure 4** is an example of a patient with prior MV repair who developed sustained monomorphic VT.

MITRAL VALVE SURGERY

Mitral valve repair should theoretically relieve stretch on the papillary muscles and facilitate ventricular remodeling, leading to a reduction in VAs. The current literature regarding the role of mitral valve repair or replacement in reducing VAs is mixed and comes from isolated case reports or single-center experiences with small sample sizes (50). Mitral valve surgery was found to be beneficial in reducing VAs in a few studies including younger patients (~42 years of age) but not in older patients (~62 years of age) (50-52). The progressive nature of the arrhythmic substrate and extent of fibrosis in the papillary muscles, chordae tendinae, and mitral annulus with age and associated comorbid conditions are probably the reason for this observation. Furthermore, older patients can have diffuse fibrosis (rather than focal) and additional myocardial substrate such as presence of idiopathic outflow tract ectopy, which cannot be treated with surgery of the mitral apparatus alone. The role of surgical cryoablation during mitral valve surgery in patients with history of VAs has been reported with no long-term data on clinical outcomes, but it can be considered in select patients (53). A collective input from a heart team consisting of cardiac surgeons, electrophysiologists, and imaging specialists is needed for optimal decision-making.

DEFIBRILLATOR IMPLANT

Currently, there are insufficient data supporting the role of prophylactic implantable cardioverterdefibrillator implantation in patients with MVP and high-risk features. As previously mentioned, in our institution, we consider an electrophysiology study for risk stratification in patients with MVP who have evidence of a trigger (pleiomorphic PVCs) and substrate (myocardial scar in typical locations). We consider implantation of a primary prevention implantable cardioverter-defibrillator if sustained monomorphic VT was induced with up to 3 ventricular extrastimuli or sustained polymorphic VT was induced with either 1 or 2 ventricular extrastimuli (54). However, we acknowledge that there is no randomized evidence to support the use of programmed stimulation to risk-stratify patients with MVP, and this approach is based on personal practice. The and negative predictive values positive of programmed ventricular stimulation remain unknown, and both the results of stimulation could be influenced by the site of stimulation (e.g., right ventricular apex vs. closer to the LV substrate), as well as the number and coupling intervals of the extrastimuli. Therefore, although programmed stimulation could overestimate the risk of sudden death in cases where the test was "positive" or provide false reassurance if the test was "negative," it may be considered in patients with the aforementioned risk profile (trigger and substrate).

CONCLUSIONS

There is an association between MVP and SCD. It would be prudent to identify and stratify at-risk patients. A majority of patients who experienced MVPrelated sudden death had evidence of a trigger (PVCs) and the substrate (myocardial strain or fibrosis) necessary to initiate and perpetuate malignant VAs. Future longitudinal studies are needed to advance our understanding of the mechanisms of MVP-related SCD, validate existing risk factors, and identify the highest-risk patients who could potentially benefit from a primary prevention intervention.
